

Sunscald in Corn and Soybean

Key Points:

- Extreme heat and moisture stress can lead to tissue damage on the leaf surface of corn and soybeans.
- · Sunscald can occur in irrigated as well as non-irrigated
- · Sunscald causes tissue damage that generally is not yield limiting unless foliar diseases infect and spread from the damaged tissue.

Sunscald injury on a corn leaf

Sunscald in Corn

- Sunscald occurs when the rate of water movement up to and through the leaf cells cannot keep up with the rate of evapotranspiration from these leaf cells.
- Younger leaves and leaves with direct orientation to the sun are most affected.
- Tissue can have a silver/gray cast initially and then turn brown and necrotic in a few days.
- If no additional disease is present, stalk tissue will look normal.
- · Sunscald damage will not progress on the leaves.
- Injury can occur while leaves are still in the whorl.
- Water in the form of dew or from irrigation can injure tissue as high temperatures heat water on the leaf surface.
- Injury to the tassel can occur, but typically will not decrease pollination as damage is usually isolated within the field.
- · Susceptibility to sunscald differs by hybrid genetics.

Sunscald in Soybeans

- Sunscald in soybeans occurs in the same manner as corn with water heating on the leaf surface.
- Typical sunscald injury is usually found on the underside of the leaf, since soybean leaves flip upside down during the warmer part of the day.
- Sunscald in soybeans may be mistaken for <u>herbicide injury</u>, disease, or <u>spider mite</u> damage.
- If no additional disease is present, stem tissue will look normal.
- Spider mite damage may accompany sunscald;
 be sure to check the underside of the leaf for insect feeding.

Sunscald injury visible on the underside of a soybean leaf.

Comparison of sunscald injury and spider mite damage. Injury caused by spider mite feeding can be distinguished by the stippling pattern on the leaves.
